¹We are grateful to Laurent Baudry, Laurent Bilke, Herve Le Bihan and Sylvie Tarrieu (Banque de France), Johannes Hoffman (Bundesbank) and Roberto Sabbatini and Giovanni Veronese (Banca d'Italia) for sharing their data with us. We also would like to thank Anna-Maria Agresti and Martin Eiglsperger (ECB) for their assistance in the re-construction of historical time series of the German CPI sub-indices. Finally, we thanks Gonzalo Camba-Méndez, Steven Cecchetti, M. Hashem Pesaran, Jim Stock and participants to the Eurosystem Inflation Persistence Network for helpful comments on previous presentations of this research. The opinions expressed here are those of the authors and do not necessarily reflect views of the European Central Bank. Any remaining errors are of course the sole responsibility of the authors.

Abstract

An aggregation exercise is proposed that aims at investigating whether the fast average adjustments of the disaggregate inflation series of the euro area CPI translates into the slow adjustment of euro area aggregate inflation. We first estimate a dynamic factor model for 404 inflation sub-indices of the euro area CPI. This allows to decompose the dynamics of inflation sub-indices into a part due to a common "macroeconomic" shock and to sector specific "idiosyncratic" shocks. We then aggregate the dynamic equations corresponding to the inflation subindices and decompose the dynamics of this aggregate into the effects of the common and the idiosyncratic shocks. Although "idiosyncratic" shocks dominates the variance of sectoral prices, one common factor, which accounts for thirty per cent of the overall variance of the 404 disaggregate inflation series, is the main drivers of the dynamic of the aggregate. In addition, the heterogenous propagation of this common shock across sectoral inflation rates, and in particular its slow propagation to inflation rates of services, generates the persistence of aggregate inflation. We conclude that the aggregation process explains a fair amount of aggregate inflation persistence.

1 Non Technical Summary

Understanding the source and degree of inflation persistence is key both to improve our ability to forecast inflation and to discriminate among different structural models of the economy. We want to know whether shocks to inflation are likely to have a persistent effects and what sort of business cycle adjustments govern the dynamics of inflation and real output. On the latter aspect, macroeconomists disagree on the importance of price stickiness (the fact that prices are not adjusted every period) for the business cycle. If prices are sticky, i.e. do not adjust to a change in the economic situation, then real output need to adjust. However, if prices can adjust to, say, the gap between demand and supply, then this gap should be negligible. Recently, research looked into micro level prices in order to solve this controversy. Because micro prices tend to adjust relatively frequently (one a quarter on average in the US and 3 times a year in the euro area), some have concluded that price stickiness cannot explain the persistence of inflation.

However, the theory of cross-sectional aggregation of dynamic processes show that slow macroeconomic adjustments may very well be consistent with much faster average speed of adjustments at the micro level. This paper uses sectoral prices of the euro area to test whether, these explicit models of the aggregation process can solve the apparent dilemma between the flexibility of sectoral prices and the persistence of macroeconomic inflation.

To start with, aggregation is a necessary step in the construction of macroeconomic price indices from survey prices on individual goods and services. For instance, in the US the Bureau of Labor Statistics collects prices on around 80.000 goods and services each month, which are divided into 350 categories called entry level items; those data are aggregated up to the overall CPI. The link between the monthly micro price quotes for each entry level item and the aggregate CPI implies at least two layers of aggregation: The first one goes from the individual price records to the price index of the relevant subcategory. The second one relates the subcategories to the aggregate CPI. This paper focuses on this second layer.

We estimate a linear dynamic factor model for 404 sub-indices of the euro area CPI between 1985 and 2003. In the model, each inflation series depends on a macroeconomic shock, the common factor, and a subcategory (or "sectoral" thereafter) specific idiosyncratic factor. We then aggregate

back the 404 models of micro level inflation and decompose the dynamics of this aggregate into the effects of the common and the idiosyncratic shocks.

Our main findings can be summarized as follows. First, we find that one common factor accounts for 30 per cent of the overall variance of the 404 series. This share is twice as large if one focuses on low frequencies, i.e., on the persistent components of the series. Second, the propagation mechanism of shocks is highly heterogenous across sectors. This heterogeneity is the prerequisite ingredient for the aggregation mechanism to be maximally effective. Third, the implied persistence from the aggregation exercise mimics remarkably well the persistence observed in the aggregate inflation. In particular, the cross-sectional distribution of the micro parameters implies an autocorrelation function of the aggregate CPI inflation which decays hyperbolically toward zero and displays long memory. Altogether, the high volatility and low persistence, observed on average at the level of sectoral inflation, is consistent with the aggregate smoothness and high persistence.

1 Introduction

Understanding the source and degree of inflation persistence is key both to improve our ability to forecast inflation and to discriminate among different structural models of the economy. Successful out-of-sample forecasting of inflation requires in first instance to decide the appropriate degree of persistence and, eventually, of non-stationarity of the data generating process. The long adjustment of the aggregate inflation appears to be well approximated by a long memory stationary process, whose autocorrelation function decays very slowly ("hyperbolically") toward zero as the lag increases. Such a slow rate of decay has, in the case of inflation, led many empirical studies to assume a unit root behavior for aggregate inflation ¹.

Turning to models of the business cycle, price stickiness is seen by many as the key ingredient that allows micro founded DSGE models to deliver the inflation and output persistence that we see in macroeconomic data (see Sbordone, 2003, Galì and Gertler, 1999, Christiano et al., 2005, Smets and Wouters, 2003, among many others.). Critics of sticky price models have stressed that the degree of price stickiness usually assumed are far too large to make economic sense (Chari, Kehoe and Mac Grattan, 2000) ² and inconsistent with the much faster average frequency of adjustments that can be observed in the micro data (Bils and Klenow, 2004 and Dhyne et al., 2005).

However, the theory of cross-sectional aggregation of dynamic processes (see Robinson, 1978, Granger, 1980, Forni and Lippi, 1997, and Zaffaroni, 2004) show that slow macroeconomic adjustments may very well be consistent with much faster average speed of adjustments at the micro level. This paper uses sectoral prices of the euro area to test whether, these explicit models of the aggregation process can solve the apparent dilemma between the flexibility of sectoral prices and the persistence of macroeconomic inflation.

To start with, aggregation is a necessary step in the construction of macroeconomic price indices from survey prices on individual goods and services. For instance, in the US the Bureau of Labor Statistics collects prices on around 80.000 goods and services each month, which are divided into 350 categories called entry level items; those data are aggregated up to the overall CPI. The link between the monthly micro price quotes for each entry level

item, whose relative frequencies of changes has been analyzed by Bils and Klenow (2004) and Dhyne et al. (2005), and the aggregate CPI implies at least two layers of aggregation: The first one goes from the individual price records to the price index of the relevant subcategory. The second one relates the subcategories to the aggregate CPI. This paper focuses on this second layer.

We estimate a linear dynamic factor model for 404 sub-indices of the euro area CPI between 1985 and 2003. In the model, each inflation series depends on a macroeconomic shock, the common factor, and a subcategory (or "sectoral" thereafter) specific idiosyncratic factor. We then aggregate back the 404 models of micro level inflation and decompose the dynamics of this aggregate into the effects of the common and the idiosyncratic shocks.

Our main findings can be summarized as follows. First, we find that one common factor accounts for 30 per cent of the overall variance of the 404 series. This share is twice as large if one focuses on low frequencies, i.e., on the persistent components of the series. Second, the propagation mechanism of shocks is highly heterogenous across sectors. This heterogeneity is the prerequisite ingredient for the aggregation mechanism to be maximally effective. Third, the implied persistence from the aggregation exercise mimics remarkably well the persistence observed in the aggregate inflation. In particular, the cross-sectional distribution of the micro parameters implies an autocorrelation function of the aggregate CPI inflation which decays hyperbolically toward zero and displays long memory. Altogether, the high volatility and low persistence, observed on average at the level of sectoral inflation, is consistent with the aggregate smoothness and high persistence.

This work is related to a recent stream of literature that stresses the importance of understanding micro heterogeneity and the aggregation process in order to explain the dynamic properties of aggregate variables. Imbs, Muntaz, Ravn and Rey (2005) show that the persistence of aggregate real exchange rates is substantially magnified because the dynamics of disaggregated relative prices is heterogenous. Carvalho (2006) derives a generalized new Keynesian Phillips curve that accounts for heterogeneity in price stickiness across sectors and shows that the process of adjustment to nominal shocks tends to be more sluggish than in comparable identical firms economies. Altissimo and Zaffaroni (2004) present an exercise similar to the

one produced in this paper where they show that the properties of aggregate income for the US can be reconciled with the dynamic properties of a cross section of individual level income extracted from the PSID panel.³

The paper is organized as follows. The following section presents the elements of cross-section aggregation relevant to our analysis. Section 3 presents the data used in the empirical analysis and addresses the presence of common factors across the price sub-indices. Section 4 introduces the micro model and the estimation methodology; furthermore such Section shows the estimation results and their implications for the aggregate persistence. Section 7 concludes.

2 Aggregation of heterogeneous AR(1) models

In this section we revisit, by means of examples, the relevant results on contemporaneous aggregation of heterogeneous ARMA models, when the number of units gets arbitrarily large (see Robinson, 1978, Granger, 1980, and Zaffaroni, 2004). For sake of simplicity, let the i th sub-index be described by an $AR(1)$ model

$$y_{it} = \alpha_i y_{it-1} + \eta_{it}, \quad (1)$$

where both the coefficients and the random shocks vary across units. When considering an arbitrarily large number of units, a convenient way to impose heterogeneity is to assume that the coefficients α_i are *i.i.d.* random drawn from some underlying distribution with probability density function $f(\alpha)$. Stationarity of each of the y_{it} then requires $|\alpha_i| < 1$ *a.s.* or, alternatively, that $f(\alpha)$ has support $(-1, 1)$. The random shock is the sum of a common

³On a related issue, Caballero and Engel (2005) have shown that if the adjustment process is lumpy or step-wise then estimating the speed of adjustment by linear method tend to over-estimate the speed of adjustment and that this effect washes out in the case of cross sectional aggregation but at a very low speed. Their result can be regarded as a criticism to the common practice of using linear method to measure persistence.

Clark (2003) and Boivin et al.(2006) also stress the importance of the decomposition of sectoral price dynamics into common aggregate shocks and sectoral idiosyncratic ones. They however do not model the aggregation process and its impact on inflation persistence.

and of an idiosyncratic component

$$\eta_{it} = u_t + \epsilon_{it}, \quad (2)$$

with the u_t being an *i.i.d.* sequence $(0, \sigma_u^2)$ and ϵ_{it} being an *i.i.d.* sequence $(0, \sigma_{\epsilon_i}^2)$. The $\epsilon_{i,t}$ are also assumed independent across i th. The aggregate variable is simply the sample average of the individual units.

It is well known that summing a finite number of ARMA processes yields again an ARMA process. For example, the sum of n distinct AR(1) models, with different auto-regressive parameters, yields an ARMA($n, n - 1$). However, when n goes to infinity, it turns out that for a continuous $f(\alpha)$, the limit of the aggregate as $n \rightarrow \infty$ will not belong to the class of ARMA processes, in contrast to the individual y_{it} . We explore such a case.

In view of (2), by stationarity and linearity of the individual models it follows that

$$Y_{n,t} = \frac{1}{n} \sum_{i=1}^n \frac{u_t}{1 - \alpha_i L} + \frac{1}{n} \sum_{i=1}^n \frac{\epsilon_{it}}{1 - \alpha_i L} = U_{n,t} + E_{n,t}, \quad (3)$$

meaning that the aggregate could be decomposed into a common and idiosyncratic component. Although the statistical properties of each unit are well-defined, conditioning on α_i , knowledge of the entire history of each y_{it} , or even of a finite number n of them, is uninformative with respect to the distribution, $f(\alpha)$. However, when looking at an arbitrarily large number of units, the distribution $f(\alpha)$ will then entirely determine the properties of the limit aggregate, which we define as the limit of the $Y_{n,t}$ for $n \rightarrow \infty$.

To this end, let us focus on the common component. This can be written as

$$U_{n,t} = u_t + \hat{\mu}_1 u_{t-1} + \hat{\mu}_2 u_{t-2} + \dots + \dots, \quad (4)$$

setting $\hat{\mu}_k = \frac{1}{n} \sum_{i=1}^n \alpha_i^k$ for every k . When n gets large, by the strong law of large numbers, each $\hat{\mu}_k$ will converge *a.s.* to the population moments of the α_i , i.e. $\mu_k = \int \alpha^k f(\alpha) d\alpha$. The dynamic pattern of the μ_k represents the *impulse response* of the common shocks u_t on the aggregate.

The dynamic pattern of the μ_k uniquely depends on the shape of the density $f(\alpha)$ and in particular on its behavior around the unit root. In particular, Zaffaroni (2004) shows that for any distribution whose behavior around unit root can be represented, up to a scaling coefficient, as $(1 -$

$\alpha)^{q-1}$, $q > 0$, then it follows $\mu_k \sim ck^{-q}$ as $k \rightarrow \infty$, where \sim denotes asymptotic equivalence. Thus, an exponential rate of decay of the impulse response of the micro units (α_i^k) corresponds to an hyperbolic rate of decay for the aggregate (k^{-q}), that depends on q . The smaller q , the denser the $f(\alpha)$ distribution around the unit root (i.e. more micro units are very persistent), the longer it takes for μ_k to converge towards zero (recall that $q > 0$ for $f(\alpha)$ to be integrable and thus be a proper pdf).

To further illustrate this result, let us consider the following parametrization of $f(\alpha)$

$$f(\alpha) = \begin{cases} B^{-1}(p, q)\alpha^{p-1}(1 - \alpha)^{q-1}, & 0 \leq \alpha < 1, \\ 0, & \text{otherwise,} \end{cases}$$

corresponding to the Beta(p, q) distribution, with parameters $p, q > 0$. Table 1 reports the dynamic pattern of μ_k for various values of q with the mean of Beta(p, q) set equal to 0.8 ($\mu_1 = 0.8$).⁴ The results are contrasted with the case of homogeneous AR(1), with impulse response given by μ_1^k (auto-regressive coefficient equal to μ_1). This example illustrates the effect of aggregation taking, as a benchmark, the case where all sub-indices are similar AR(1) processes with a root equal to 0.8, i.e are quite persistent.

Table 1: Impulse response functions of limit aggregate U_t

k	$f(\alpha)$				μ_1^k
	$q =$	0.2	0.7	1	
1	0.8	0.8	0.8	0.8	0.8
2	0.72	0.67	0.66	0.65	0.64
5	0.61	0.48	0.44	0.37	0.33
10	0.54	0.33	0.28	0.17	0.11
50	0.39	0.12	0.07	0.01	1.4×10^{-5}
200	0.36	0.09	0.05	0.01	4.1×10^{-20}

The effects of heterogeneity and aggregation are substantial: the impulse response function of the aggregate process (common component) decays towards zero with a much slower decay than the homogeneous coefficient case. Note that the smaller q is, the larger is the mass of the distribution around the unit root and the slower will the effect of random shocks fade away. In

⁴In order to consider Beta(p, q) distributions with different q but same mean $\mu = 0.8$, one needs to set $p = \left(\frac{\mu}{1-\mu}\right) q$.

other words, the average impulse response is markedly different from the impulse response of the average.

The characterization of the impulse response implies a neat representation of the auto-covariance function (ACF) and spectral density of the limit aggregate U_t . In particular, when $q > 1/2$, the autocovariance function of the limit aggregate process satisfies

$$\text{var}(U_t) < \infty, \quad \text{cov}(U_t, U_{t+k}) \sim ck^{1-2q} \quad \text{as } k \rightarrow \infty, \quad (5)$$

with c being an arbitrary scaling constant. One can easily see that $\text{cov}(U_t, U_{t+k})$ decays toward zero albeit at an hyperbolically rate. When $q > 1$, the density f will have little mass around the unit root ($f(\alpha) \downarrow 0$ as α approaches 1) and the $\text{cov}(U_t, U_{t+k})$ is summable, meaning that it decays to zero sufficiently fast. This is known as a case of *short memory*. Instead, when $1/2 < q < 1$, large mass of the $f(\alpha)$ will be around the unit root ($f(\alpha) \uparrow \infty$ for α approaching 1). For this case, the $\text{cov}(U_t, U_{t+k})$ still decays toward zero but too slowly to ensure summability, resembling the classical definition of long memory. In particular, we say that U_t is a stationary process displaying long memory with *memory parameter* $0 < d < 1/2$ whenever

$$\text{cov}(U_t, U_{t+k}) \sim ck^{2d-1}, \quad \text{as } k \rightarrow \infty. \quad (6)$$

The previous Beta distribution example yields a particular case of (6) setting $d = 1 - q$. Hence, the smaller is q , the larger is the frequency of units whose α_i is close to unity, and the more persistent is the limit aggregate. Finally in the extreme case when $0 < q < 1/2$, the aggregate process will be non stationary; this is evident since the autocovariance function does not even decay to zero as k increases.

Two final remarks are warranted. First, the idiosyncratic component can be neglected as long as the aggregate is stationary, because their effect should vanish through aggregation. However, in the case of non-stationary aggregate, namely $0 < q < 1/2$; the idiosyncratic components of the very persistent micro processes can still show up in the aggregate. Second, the above results can be extended within a general ARMA framework where the implication for aggregation depend on the shape of the distribution of the largest autoregressive root of the ARMA process (See Zaffaroni (2004) for more details).

3 The data

The data consist of 404 seasonally adjusted quarter over quarter (q-o-q) inflation rates of CPI sub-indices from France, Germany and Italy. In this section, we first discuss our choice of data and sample period. Second, we present descriptive statistics on sectoral and aggregate inflation and their persistence. Finally, we propose some evidence on the presence of a common driver among the 404 inflation subindices.

3.1 Choice of data and sample period

We use CPI data rather than HICP because the latter are available only since 1995. However, because earlier data are not readily available in all the countries of the euro area, we limited our data to France, Germany and Italy. These countries together account for roughly 70 per cent of the euro area population and consumption. The three CPI original databases together comprise 470 sub-indices. 66 of these were not suitable for estimation of an ARMA either because they have too few observations (e.g. some sub-indices are available only since 2000), or because they correspond to items which prices are set at discrete intervals (e.g. Tobacco or Postal services). We are left with 404 "well-behaved" series that are proper to be modeled.⁵

We focus on the post 1985 data for two reasons. First, the German data are not available beforehand. Second, many studies have showed that the mid-eighties marked a significant break in average inflation in most OECD countries. Corvoisier and Mojon (2005) suggests that Italian, French and German time series of inflation all admit a break in the mid-eighties. Bilke (2005) obtains that most of the 148 French sectoral inflation rates (exactly our data as far as France is concerned) admit a break in their mean around 1985 and very infrequently at any other time of the 1972-2003 sample period. Bilke argues that this coincidence of changes in the dynamics of sectoral inflation rates may actually reflect a major shift in French monetary policy regime in the mid-1980's. According to Gressani, Guiso and Visco (1988), such a regime shift is also very likely to happen at about the same time in Italy. As regards Germany, where the monetary policy regime was more

⁵See the appendix for the source of the data and the data treatment.

stable, the breaks in average inflation of its two largest trade partners is a major event in itself.

For all these reasons, we deem the post-1985 sample as appropriate to study the persistence of inflation in the euro area. This choice of sample leaves us up to 77 observations of q-o-q inflation rates for each of the 404 sub-indices.

3.2 Sectoral inflation series: descriptive statistics

We now turn to the properties of the sub-sector inflation rates. Table 2 reports descriptive statistics of aggregate inflation and of the distribution of the 404 sectoral inflation rates. First, the inflation sectoral means are quite disperse with fifty per cent of their distribution ranging from 1.8 to 4.2 percent. The mean of aggregate inflation is 2.6 percent. Second, sectoral inflation is noticeably more volatile than aggregate inflation. On average, the standard deviation of the inflation sub-indices is equal to 3.5 percent, i.e. nearly three times as large the one of the aggregate. This much higher volatility is a common feature of the inflation rates of sectoral prices as shown in Bilke (2005) and Clark (forthcoming). Third, the persistence of sectoral inflation rates is also clearly smaller than the one of the aggregate inflation series. The largest root of the ARMA fitted to the aggregate inflation amounts to 0.93.⁶ This roughly equals to the 75th percentile of the sector's persistence.

If the sectoral data would already display long memory, so that (6) holds for the large majority of the sub-indices inflation rates, then the aggregation exercise would be trivial. The last column of the table, which reports the statistics relative to the distribution of estimated long memory parameters⁷, confirms that only very few sectoral inflation rates exhibit fractional integration. d is not different from or close to -0.5 for a vast majority of the cross-section. However, as shown below, our estimate of d for the aggregate inflation rate is 0.18, well above the 90th percentile of the sectoral d parameters (-0.18). Fourth, we observe sharper differences in persistence across the main sectoral groupings of the CPI (processed food, unprocessed

⁶The largest root is the one associated to the best ARMA(p, q) as selected by the Akaike (AIC) criteria with $0 \leq p, q \leq 4$, estimated on the q-o-q inflation time series for the 1985q2-2004q2 sample, using the ARMAX procedure of `MatLab`.

⁷We use the parametric Whittle estimator (see Brockwell and Davis, 1991).

food, energy, non-energy industrial goods-NEIG- and services) than across countries. The gap between the ARMA largest root of the inflation process of unprocessed food prices (0.52) and one of the energy (0.78) is wider than between the root associated to the ARMA processes fitted on the inflation of German, French and Italian prices. Comparing the main groupings of CPI sub-indices across countries, we also find that the sectoral hierarchy at the euro area level applies within each country.

To conclude, we find clear evidence that the inflation rates of the individual sub-indices are way more volatile and much less persistent than the inflation rate of the aggregate CPI index. Moreover, volatility and persistence are more sector than country dependent.

Table 2: Descriptive statistics of the 404 sectoral inflation rates
(first two columns annualized q-o-q inflation rates)

	Mean	Stand. dev.	Larg. ARMA root	Long mem. d

3.3 Behind the aggregation mechanism: common shock and heterogeneous parameters

This section assesses the two elements that play a crucial role in shaping the effect of cross-section aggregation of time series: the presence of common shocks and the heterogeneity in the propagation mechanism of those shocks. This means that, using the notation of Section 2, there is a common shock u_t and that the α_i are different across i . We start by investigating the presence of common shocks in the cross-section of the inflation sub-indices before enquiring on the heterogeneity in the propagation of this common shock across sectors.

Following the recent literature on factor model in large cross-sections⁸ we estimate the first ten dynamic principal components of the autocovariance structure of the sectoral inflation series. The dynamic principal component analysis provides indications on the number of common shocks explaining the correlation structure in the data (see Forni et al., 2000).

Figure 1 presents the spectrum of the first ten dynamic principal compo-

⁸See Forni et al. (2000), Stock and Watson (2002) and the application by Clark (forthcoming) to US disaggregate consumption deflators.

nents⁹ of the 404 inflation time series.

Figure 1: First ten principal components.

The variance of sectoral inflation is strikingly dominated by one common factor. Figure 1 also shows that this first common factor is the only one of which the spectrum is concentrated on low frequencies. Hence this factor is the driver of persistence observed in sectoral inflation.¹⁰ The other factors account for a much smaller share of the variance than the first one. And, they are also more equally relevant at all frequencies, as indicated by their

⁹Dynamic principal components are calculated as the eigenvalue decomposition of the multivariate spectra of the data at each frequency (see Forni et al. (2000) for details). The autocovariance function up to eight lags has been used in the construction of the multivariate spectral matrix. The data has been standardized to have unit variance before estimating the multivariate spectra.

¹⁰The height of the spectrum at frequency zero is a well-known non parametric measure of the persistence of a time series.

relatively flat patterns in Figure 1.¹¹

On the basis of these results, we opt for a factor model of the sectoral inflation series that admits a *single common shock*. We then model the sectoral inflation time series as:

$$y_{it} = \delta_{0i} + \Psi_i(L)u_t + \xi_{it}, \quad i = 1, \dots, N \quad (7)$$

where u_t is the common shock, ξ_{it} is a stationary idiosyncratic component, orthogonal to the common one and δ_{0i} is the constant term. $\Psi_i(L)$ is a unit specific lag polynomial which represents the propagation of the common shock through the y_{it} process.

We now look at whether the propagation mechanism of the common shock in the cross-section of price sub-indices is homogenous across items. Still resorting to spectral analysis, we estimate the coherence of the first principal component and each one of the 404 series, in order to obtain "correlation" at different frequencies. Figure 2 reports the cross-section distribution of the squared coherence values at three frequencies: zeros, $\pi/6$ (three years

¹¹These findings are in line with Clark (2003)'s results. He also shows that the common factor of the disaggregate US inflation rates is more persistent than the idiosyncratic components.

periodicity) and $\pi/2$ (yearly periodicity) respectively.

Figure 2: Distribution of the squared coherence.

The differences in the mode and the shape of the histograms across the three frequencies is a first confirmation of the presumption that the common shock transmission to sectoral inflation is heterogenous. The following section models this heterogeneity.

4 Model: specification and estimation

4.1 The model

The quarterly rate of change of each sectoral price sub-index is assumed to behave according to (7):

$$\begin{aligned} y_{it} &= \delta_{0i} + \Psi_i(L)u_t + \xi_{it} \\ &= \delta_{0i} + \frac{\Lambda_i(L)}{A_i(L)}u_t + \frac{\Gamma_i(L)}{A_i(L)}\epsilon_{it}, \end{aligned} \tag{8}$$

with $u_t \sim i.i.d. (0, 1)$ and $\epsilon_{it} \sim i.i.d. (0, \sigma_i^2)$, $i = 1, \dots, N$. The above polynomials in the lag operator satisfy $\Lambda_i(z) \neq 0$, $\Gamma_i(z) \neq 0$, $A_i(z) \neq 0$ $|z| \leq 1$. Each y_{it} behaves as a stationary $ARMA(p_i, q_i)$ with a possibly non zero mean, where $1 \leq p_i, q_i \leq 2$, in the estimation part, and the order q_i, p_i of the models are estimated based on the Akaike criteria. Note that we are imposing that the common part, involving the u_t , and the idiosyncratic part, involving the $\epsilon_{i,t}$, have the same autoregressive structure but they are not constrained in the moving average part. Moreover, for the sake of simplicity, we are also assuming that both the common and the idiosyncratic component have an MA component at most of order q_i in both cases. These assumptions simplify greatly the estimation procedure and, at the same time, allow a sufficiently rich dynamics. Note, however, that the sectoral coefficients are estimated freely so that, for example, the parameters in $\Lambda_i(L)$ and $\Gamma_i(L)$ are sector specific.

4.2 The estimation strategy

The estimation of model (8) is non standard. First, the large dimensionality (large N) rules out the recourse to the conventional Kalman filter approach. Second, the recent techniques for estimation of dynamic factor models, all based on the principal component approach such as Stock and Watson (2002) and Forni et al. (2005), would be inappropriate in our model due to the presence of sector specific autoregressive components, $A_i(L)$. This is why we estimate the parameters of the model (8) by means of a multi-stage procedure:

- (i) For each unit i , we estimate an $ARMA(p_i, q_i)$ with non-zero mean but

without distinguishing between the common and the idiosyncratic component. In fact the sum of two moving average components of finite order,

$$\Lambda_i(L)u_t + \Gamma_i(L)\epsilon_{it} \equiv B_i(L)z_{it},$$

turns out to be an *MA* of the same order with polynomial $B_i(L)$ and an innovation sequence $z_{i,t}$. Moreover, we do not need to specify the coefficients of $B_i(L)$ as a function of the coefficients $\Lambda_i(L)$, $\Gamma_i(L)$, in order to obtain consistent estimate of the constant term, δ_{0i} , and of the coefficients of autoregressive part, $A_i(L)$;

(ii) we average the estimated MA component $\hat{B}_i(L)\hat{z}_{i,t}$ across i . This yields an estimate $\hat{x}_t^{(N)}$ of $\left(N^{-1} \sum_{i=1}^N \Lambda_i(L)\right) u_t$, where the approximation improves as N grows since, as $N \rightarrow \infty$, the idiosyncratic component $\left(N^{-1} \sum_{i=1}^N \Gamma_i(L)\epsilon_{i,t}\right)$ vanishes. Thus we fit a finite order *MA* to the estimated $\hat{x}_t^{(N)}$ and obtain an estimate of the common innovation \hat{u}_t ;

(iii) using the \hat{u}_t as an (artificial) regressor, we fit a *ARMAX*(p_i, q_i, q_i) process (an *ARMA* process with exogenous regressors) to each y_{it} , in order to obtain also consistent estimate of the coefficients of $\Lambda_i(L)$ and $\Gamma_i(L)$.

The steps (ii) and (iii) of the procedure can be iterated in order to improve the estimate of the common shock as well as of the autoregressive parameters. Such procedure does not require any distributional assumption. Implicitly it requires that both N, T to diverge to infinity with N/T decreasing toward zero, or at most with N, T diverging at the same rate. Estimation of each of the *ARMA* and *MA* processes is carried out using the Kalman filter¹². Details can be found in Altissimo and Zaffaroni (2004).

4.3 Results

4.3.1 Results for sectorial inflation rates

This section briefly describes the estimates of over three thousand parameters (8 parameters for each of the 404 time series) of the model. First, the estimated common shock u_t turns out to be white, with a non-significant

¹²The described iterative procedure is similar to a recent modification of the EM algorithm for the estimation of factor models in the presence idiosyncratic autoregressive components proposed independently by Stock and Watson (2005).

autocorrelation, corroborating the *i.i.d.* hypothesis. Second, we compare (in Figure 3) the distribution of the first loading of the common shock, which is a measure of the size of the effect of the common shock in the individual time series, with the cross-sectional distribution of the standard deviation of the idiosyncratic components. The idiosyncratic volatility σ_i is substantially larger than the common shock volatility, six times larger. The median of the distribution of the estimated first loading is 0.06, whereas we obtain 0.38 for the standard deviation of the idiosyncratic component. This strikingly confirms that most of the variance of sectoral prices is indeed due to sector specific shocks.

Figure 3: Distributions of λ_{0i} and σ_i .

Third, we turn to $A_i(L)$, which dominates the dynamic effects of the common shock on sectoral inflation. In Figure 4 we report the distribution of the

signed modulus of the maximal autoregressive root of such polynomials.¹³ This distribution is dense near unity with a median of 0.82, a mode at 0.93 and a long tail to the left.

Figure 4: Max autoregressive roots.

Fourth, we compare the dynamics of sectoral inflation rates and main CPI groupings in Table 3. The Table reports the number and the relative frequency of series having roots above given thresholds in specific sub-category as well as the total weight of such series in the overall CPI.

Table 3: Summary statistics of estimated parameters for sectorial inflation rates

¹³We did sign such modulus so that we could distinguish between the effect of a negative root from a positive one and also consider the effect of complex roots.

	#	CPI weight	Largest root >0.875			Largest root >0.925		
			#	freq	CPI weight	#	freq	CPI weight
EA3	404	1	142	0.35	0.48	54	0.27	0.26
Germany	87	0.42	31	0.34	0.23	11	0.12	0.14
France	147	0.30	55	0.38	0.15	23	0.17	0.06
Italy	170	0.28	56	0.35	0.11	20	0.12	0.06
Processed food	65	0.14	9	0.14	0.03	2	0.03	0.01
Unprocessed food	42	0.07	7	0.17	0.01	3	0.07	0.00
Non-energy ind. goods	167	0.33	68	0.42	0.14	25	0.15	0.08
Energy goods	18	0.07	8	0.50	0.05	5	0.31	0.03
Services	114	0.39	50	0.44	0.25	19	0.17	0.14

Looking at the cross country pattern, highly persistent sub-sectors in Germany account for a much larger share of the overall euro area CPI; this effect is mainly due the high persistence (autoregressive root of 0.96) of German housing expenditure inflation¹⁴, which accounts for around 10 per cent of the overall CPI. Furthermore, while Energy and Service has the highest frequency of persistent series, Services and, to some degree, Non-energy industrial goods sub-sectors turn out to be more relevant for the dynamics of aggregate inflation because they have a higher weight in the consumption basket.

4.3.2 Results for aggregate inflation rate

Given the estimates of the micro parameters, we are now in a position to infer the dynamic properties of the aggregate induced by the behavior of the micro time series. We consider three different types of aggregation schemes. First, we reconstruct the aggregate as an exact weighted average of the individual micro time series and in this way we exactly recover the contribution

¹⁴The subindex is apartment rent (incl. the value of rent in case of owner-occupied houses), which account for around 20 per cent of the German CPI, while it is only 3 per cent of the Italian and French.

of the common shocks to the aggregate inflation and to aggregate persistence. Second, we exploit the theoretical link between the distribution of the largest autoregressive root of sectoral inflation rates and the autocovariance structure of the aggregate, as presented in section 2, to infer the dynamic properties of the latter. Third, we consider a so-called naive aggregation scheme based on the (wrong) presumption that the aggregate model has the same functional form as the individual models, in our case an ARMA.

Exact aggregation

The aggregate inflation data is defined as the weighted average of the sectoral inflation rates.¹⁵ Therefore using the estimates of the model in (8) it follows:

$$\begin{aligned}
Y_{n,t} &= \sum_{i=1}^n w_i y_{it} \\
&= \sum_{i=1}^n w_i \hat{\delta}_{0i} + u_t \sum_{i=1}^n w_i \frac{\hat{\Lambda}_i(L)}{\hat{A}_i(L)} + \sum_{i=1}^n w_i \frac{\hat{\Gamma}_i(L)}{\hat{A}_i(L)} \epsilon_{it} \\
&\equiv \hat{\delta}_0 + \hat{\Psi}(L)u_t + \hat{\xi}_t
\end{aligned}$$

where the w_i are the euro area CPI weights. So the aggregate inflation is decomposed into two components, one associated with the common shocks, u_t , and its propagation mechanism, $\hat{\Psi}(L)$, and a second associated with the micro idiosyncratic process, ξ_t . Figure 5 shows the reconstructed aggregate, $Y_{n,t}$, versus its common component, $\hat{\Psi}(L) \times u_t$. There is a high correlation between the two components, around 0.76, but the former is clearly more volatile pointing to the fact that the idiosyncratic component ξ_t is still relevant in the aggregate. We however stress that given that the idiosyncratic component has little persistence, $\hat{\Psi}(L) \times u_t$ constitute a new measure of core inflation that can be of direct relevance for monitoring and forecasting

¹⁵Statistical offices do not aggregate inflation rates but first they aggregate price indices and then compute the aggregate inflation rate. Here we ignore the possible effect induced by such non-linear transformation. In fact it can be shown that this is not relevant for the dynamic properties of the aggregate.

inflation.

Figure 5: Aggregate inflation (solid line) and common component.

The aggregate propagation mechanism, $\widehat{\Psi}(L)$, is a weighted average of the propagation at micro level, $\widehat{\Psi}_i(L)$ and its estimates can be used to recover the autocovariance structure of the component of the aggregate inflation that is driven by the common shock, i.e.: $\widehat{\Psi}(L) \times u_t$. The upper panel in Figure 6 shows the autocovariances of aggregate inflation, $Y_{n,t}$, (solid line) versus the one of $\widehat{\Psi}(L) \times u_t$ (dotted line), while the lower panel reports the average

autocovariance of micro process.¹⁶

Figure 6a: Autocovariances aggregate (solid) and common component.

¹⁶Two graphs were needed given the different scale of the results.

Figure 6b: Average autocovariance.

The autocovariance of the reconstructed common components tracks well the covariance structure of the aggregate data, in particular in term of its decay. The variance of the aggregate inflation remains larger than the one of the common component, i.e. the component associated with micro idiosyncratic noise is still relevant in the aggregate data, even if it seems to have little or no dynamic structure. The contrast between the results across the two panels of Figure 6 is even more striking. Average contemporaneous variance of the micro data is an order of magnitude larger than the one of the aggregate data or of the common component in the aggregate data but it decays to zero very quickly. Finally, Figure 7 compares the autocorrelation of the aggregate and the one of the common component. The same conclusion emerges. The common component is the main driver of the dependence of the aggregate

data and it properly captures the slow decay of autocorrelation of the data.

Figure 7: Autocorrelation of aggregate inflation (solid line) and of the common component.

Asymptotic aggregation

The above discussion has been based on the analysis of the exact autocovariance structure of the common component, given that in the exercise at hand we have the knowledge of all the relevant micro processes. Similar conclusion can also be derived by analyzing the cross-sectional distribution of the largest root of the autoregressive part (Figure 4) using the analytic apparatus presented in Section 2.

However we first need to take into account that sectors have different weights in the aggregate. Therefore the distribution in Figure 4 which depicts the distribution of the 404 maximal roots is not directly relevant because the weighting scheme in the aggregation can change the relative importance of the sectors for the dynamics of the aggregate. To overcome this problem, we implement a relative re-weighting of the 404 maximal autoregressive roots in function of the relative weights of the respective sectors. Precisely, we

bootstrap a sample of 10.000 data out of the 404 roots with relative frequency equal to the weighting scheme; hence roots associated to sectors with a larger weight will be re-sampled more often. The density function associated to this simulated sample is compared to the equal weight one in Figure 8.

Figure 8: Renormalized distribution of max autoregressive root (solid) and original one.

The implication for aggregation are associated to the behavior near unity of such new distribution. In particular, the above distribution can be approximated near unity as

$$\hat{f}(\alpha) \sim c(1 - \alpha)^{-0.13} \text{ as } \alpha \rightarrow 1^-,$$

implying that our estimate of the q as in Section 2 is equal to 0.87. Following (5) in Section 2 and the results in Zaffaroni (2004), it is possible to show that the autocovariance function (ACF) of the common component of the

aggregate, $\widehat{\Psi}(L) \times u_t$, satisfies:

$$\text{cov}(\widehat{\Psi}(L) \times u_t, \widehat{\Psi}(L) \times u_{t+k}) \sim c k^{-0.74} \quad \text{as } k \rightarrow \infty.$$

According to definition in Section 2, the process has long memory with parameter $d = 0.13$. Therefore, the common component of the aggregate inflation appears to be a stationary but long memory process. Therefore, the ACF decays toward zero with an hyperbolic decay, and thus is markedly different from the behavior of the sectoral inflation processes.

Moreover, we estimate the memory parameter using now the aggregate reconstructed data using the Whittle parameteric estimator (see Brockwell and Davis, 1991). The direct estimate of the memory parameter on aggregate data turns out to be equal to 0.18, with standard error of the estimate equals to 0.24, which, given the distribution reported in the last column of Table 2, is reasonably close to 0.13, as recovered from the micro structure. Therefore, the aggregate data presents a long memory behavior that is not present in the micro time series; such a long memory behavior appears to be fully accounted for by aggregation.

Naive aggregation

The above results are framed in term of autocovariance function and they show why the difference in persistence between the micro dynamic and macro one are not necessarily inconsistent. Another way to highlight the effects of aggregation on persistence is to consider the following naive exercise.

We construct an hypothetical *ARMA* process, whose roots are the mean of the individual roots of the 404 estimated *ARMAs*. Then we contrast the impulse response function to a common shock of such a hypothetical *ARMA* with the one of the common component, $\widehat{\Psi}(L) \times u_t$. The idea of the exercise is to see the aggregate response to shock in case the propagation mechanism is equal across agents versus the case of different propagation mechanisms, i.e., to quantify the effect of heterogeneity and aggregation¹⁷. Figures 9 compares

¹⁷See also the presentation of similar exercises in the context of microfounded model, though on hypothetical distribution by Carvalho (2006).

the impulse response for the ARMA and the one implied by $\widehat{\Psi}(L)$.

Figure 9: Impulse response of the common component and of the naive ARMA.

The exercise is quite instructive. In the case of a homogeneity of the micro propagation mechanism, after four years (16 periods on the x axis in Figure 9) a shock u_t would be completely absorbed, while in reality, due to the presence of heterogeneity and of some very persistent micro units, around 20 per cent of the original shock has not been absorbed.

Summarizing, we can claim that the analysis of the micro determinants of the aggregate inflation supports the view that aggregate inflation in our sample period can be well described by a stationary but long memory process. We have shown that starting from very simple ARMA process at micro level we have been able to properly reconstruct the dynamic properties of the aggregate. We have also shown that the micro volatility and low persistence can be squared with the aggregate smoothness and persistence.

5 Conclusion

In this paper, we build on the heterogeneity in the inflation dynamics across CPI sub-indices and investigate the role played by cross-sectional aggregation in explaining some of the difference observed between micro and macro evidence regarding inflation dynamics. We focus in particular on the link between CPI sub-indices and the aggregate CPI.

We estimated time series models for 404 sub-indices of “items/sectors” of euro area CPI between 1985 and 2003. We fitted ARMA processes at micro level distinguishing the propagation mechanism of the common and idiosyncratic shocks. Our first result is that the propagation mechanism of shock at micro level across sectors is very heterogeneous. This heterogeneity implies a non trivial link between sectoral and aggregate persistence. We perform an aggregation exercise and compute the aggregate persistence as a function of the 404 sectors persistence. Our model is able to square the volatility and low persistence observed, on average, at the level of sectoral inflation with the smoothness and persistence of the aggregate. The persistence that we obtain through this aggregation exercise mimics remarkably well the persistence observed in the aggregate inflation. In particular, aggregate inflation turns out to be a stationary but long-memory process and the persistence of the aggregate inflation is mainly due to the high persistence of some sub-indices mainly concentrated in the service sector, such as housing cost in Germany.

Altogether, this paper demonstrated the importance of heterogeneity and aggregation for understanding the persistence of inflation at the macroeconomic level. We leave the design and estimation of stylized models of the business cycle that can be consistent with both heterogeneity at the micro level and the implied persistence at the macro level for future research.

Data appendix

The French CPI sub-indices

The French data consist of 161 monthly sub-indices. They are available since 1972 and they have been back-dated the INSEE CPI (1998 base year). The later is publicly available since 1990 for 148 sub-indices while the prices of 13 items enter the CPI basket only after this date.

The German CPI sub-indices

The German data consist of 100 prices of the 3 Digits classification of HICP sub-indices. These prices are available monthly from early 90s to 2004.

To back date the HICP, we used about 150 3-digits sub-indices of the 1990 base year CPI data, which are available between 1985 and 1995.

The Italian CPI sub-indices

The Italian data consist of 167 monthly indices underlying the Italian CPI constructed by ISTAT. The data, kindly provided by the Bank of Italy Research Department, start in 1980 and were rebased to 1995 equal to 100. The full list, and corresponding description, of the sectors is available upon request from the authors.

Seasonal adjustment

The data were seasonally adjusted with TRAMO-SEATS. The main advantage of this routine is that it is used regularly for the official HICP statistics, and that it allows for integrated seasonal components. This latter aspect is particularly important for our data because EUROSTAT has required that, from the mid-1990's on, the biannual sales campaigns are reflected in the HICP sub-indices of interest. This may affect in particular our French and our German data. As a matter of facts, the Banca d'Italia keeps track of the prices both with the new method and consistently with the historical data. And we used the historically consistent series.

In the seasonal adjustment procedure, we utilized the longest available monthly series, i.e. 1972-2004 for France, 1981-2004Q2 for Italy and 1985-2004 for Germany.

The monthly price level has been transformed into quarterly average and the analysis has been performed on quarter on quarter inflation rates. We use this frequency both to limit the noise of the monthly series and to compare

directly our results with the business cycle literature and available studies of sectoral inflation in the euro area (e.g. Lünnemann and Mathä, 2004) and elsewhere Cecchetti and Debelle (2004).

Data cleaning

We further clean our data according to the following steps. First, we eliminate all the series that start only in the mid 1990's. This is because these series do not have enough degrees of freedom to carry out the estimation of ARMA models. We exclude from our sample 8 French and 9 German sub-indices that are available only after 1995, 1998 or 2000.

Second, we eliminate all the series which are adjusted at rare discrete steps. The typical such series include the price of Tobacco or mailing services. We exclude 6 German, 4 French and 12 Italian sub-indices of this type.

Altogether we keep 404 sub-indices out of the 444 available in the initial dataset, 377 of which are available from 1985 Q1 to 2004Q2. A last step before, the estimation is to corrections of outliers in the inflation series. We filter out these outliers by replacing observations that are more than 3 standard deviations away from the time series mean of each inflation series by a local median observation. This outlier correction mainly eliminates discrete shifts in the levels of the price indices.

Figure A1 plots the time series of the aggregates that we can reconstruct from the well-behaved inflation series at the national level and for the aggregate of the three countries (using 1995 PPP-GDP weights of 0.422, 0.296 and 0.282 for Germany, France and Italy, respectively) together with the official CPI inflation rate. We take from the picture that our sub-set of well-behaved sectoral inflation series offers, when aggregated, a reasonable approximation of the official aggregate index.
